1. Introduction

Intensive agricultural production has increased over the last 100 years, and agricultural land now makes up over a third of ice-free land on Earth (Ramankutty *et al.* 2018). This has allowed increases in human population and increased global stability in production (Foley *et al.* 2011). However, this is not without cost, as higher-diversity non-crops are converted to lower-diversity crops, resulting in loss of habitat and overall biodiversity of non-target organisms. Maintaining both biodiversity and production in agroecosystems represents a goal of conservationists and agronomists, and holds the potential for win-win scenarios (“multifunctionality” *sensu* Mitchell *et al.* 2014; Frei *et al.* 2018; but see also Karp *et al.* 2018). Key to this goal is the preservation of semi-natural land (SNL) in and around crops, which represents the interface between crops and non-crops within agroecosystems.

SNL in agroecosystems is important for both agricultural production and conservation (Prieto-Benítez & Méndez 2011), and can create better biotic and abiotic conditions for crop growth (Case *et al.* 2019; Weninger *et al.* 2021; but see Lowe *et al.* 2021). SNL acts as habitat for mobile organisms, and can act as a source of ecosystem services, such as pollination or pest control (Albrecht *et al.* 2020; Gardner *et al.* 2021), but this depends on both the crop system (Gray & Lewis 2014; Quinn *et al.* 2017) and landscape context (Marja *et al.* 2019; Boetzel *et al.* 2020). SNL can also create microclimate effects that reduce extreme temperature, trap moisture, and reduce wind speed and soil erosion (Kort 1988; Brandle *et al.* 2004; Wratten *et al.* 2012). Field boundaries (e.g. grass and flower strips, tree or shrub shelterbelts, road right-of-ways) are SNL of particular interest, as they are extremely common and require less land than larger agricultural set-asides.

Semi-natural field boundaries may cause positive or negative effects on crops, depending on the spatial scale at which ecosystem services operate. Low yields near may occur near the edge of the field because of patchy seed emergence, poor microclimate, shading from trees, or greater competition with weeds (Figure 1, Scenario 2). Alternatively, yield may be higher near field boundaries (Scenario 3) if boundaries provide helpful ecosystem services (Duelli & Obrist 2003). For example, crop pollination services from bees that nest in field boundaries drops rapidly with distance (Garibaldi *et al.* 2011) and wind speed is reduced directly downwind of treelines (de Jong & Kowalchuk 1995), so positive effects will be concentrated close to the boundary. Depending on the rate at which positive and negative boundary effects decline with distance, another scenario is also possible. Yield may be maximized at intermediate distances (Scenario 4), suggesting a “Goldilocks” field size where negative edge effects are canceled out by ecosystem services (Kowalchuk & de Jong 1995; Helmers & Brandle 2005; Mitchell *et*

al. 2014; Van Vooren *et al.* 2017).

Unfortunately, data to inform these decisions are often minimal, as observing boundary effects requires large amounts of expensive and time-consuming crop yield data. This means that studies of SNL effects on crop yield tend to suffer from limited spatial scope and small sample sizes, reducing statistical power and generality (Brandle *et al.* 1984; Baker *et al.* 2018; but see also Redhead *et al.* 2020). Meta-analyses are a common solution to this problem (e.g. Albrecht *et al.* 2020; Lowe *et al.* 2021), but precision yield data holds enormous promise because of its relatively common usage and low operating costs (Steel 2017; Osorio *et al.* 2018). However, its use is limited for several reasons, namely 1) a lack of standardized formats between equipment types, 2) sensor calibration required for field-level accuracy, and 3) low familiarity with spatial statistical methods. Ecosystem services from field boundaries may influence both the mean as well as the variability of yield in agroecosystems (Redhead *et al.* 2020; Hünicken *et al.* 2021); typically only means are considered, but lower variability in yield can also be valuable from a grower’s perspective. There are few studies of yield variability (only those with large datasets), but precision yield data opens up the possibility of modeling within-field variability, as well as average yield.

In this paper we use a precision yield dataset from Alberta, Canada to ask the following questions: 1. How does crop yield change with distance from the edge of field? 2. Does this depend on type of field edge? 3. Is there an intermediate distance where yield is maximized or variance is minimized? To our knowledge, only (Osorio *et al.* 2018) has studied the effects of field boundaries using precision yield data, making this study one of the first of its kind.

2. Methods

2.1. Data collection

Precision yield data were collected directly from farmers across Alberta (Figure S1). Farmers were solicited for yield data through local agronomists, and we received 298 field-years of data from 5 growers across a total of 7 years (2014-2020). We converted raw data to a standard csv format using Ag Leader SMS®. 85% of the crop types were either wheat (*Triticum aestivum*), canola (*Brassica napus*), or peas (*Pisum sativum*), three of the most common crops in rotation in Alberta (Statistics Canada 2014). The remaining crop types had low replication, so we constrained our analysis to only field-years containing wheat (94), canola (119), or peas (39), for a total of 252 field-years of data. Individual fields ranged

from 5.9 to 369 ha in area (mean: 72.2 ha), and contained between 1 and 6 years of data (mean: 3.1), for a total of 14.4 million data points.

Yield data was collected in rectangles of the same length as the data interval (distance = combine ground speed \times interval, typically 1 second) and the same width as the combine header (5-7 m, adjusted by the combine to account for overlap with adjacent swaths). We used dry yield (tonnes of seed per hectare minus - crop moisture) as our measure of yield, using the size of each rectangle (m^2), dry yield (tonnes), and the spatial location. Because of the large number of yield rectangles per field (30-800 thousand), we used the centroid of each polygon as its location, treating areal data as point data. Seeding and application rates were constant across fields, so we did not consider inputs in our analysis. Precision yield data can be highly variable and is prone to extreme outliers, especially when combine ground speeds are low and at the beginning of rows (Griffin *et al.* 2007; Whelan & Taylor 2013), or when the combine is accelerating or decelerating (Arslan & Colvin 2002). Therefore, we used the following filtering procedure to clean the data prior to model fitting (see Appendix B for R code):

1. Removed outliers and “inliers” using the spatial filtering procedure from (Vega *et al.* 2019)
2. Removed unrealistic yield values (10.75 T/ha for wheat, 8 T/ha for canola and peas), and values of zero or less
3. Removed extremely low and high outliers (below 1st percentile, above 99th percentile) for: dry yield, steering angle differences, ground speed
4. Removed points with large changes ($>20\%$) in ground speed
5. Removed extremely low and high changes in position, indicating that the combine had stopped or moved to another part of the field between data collection
6. Sub-sampled filtered data to 50,000 data points per field (reduce computation time)

Field boundaries were digitized using buffers from the yield data locations, then manually checked using satellite imagery from Google Earth and classified land cover data (Agriculture and Agri-Food Canada 2018). Crop boundaries are flexible, and often change yearly depending on planting and emergence conditions. For example, ephemeral wetlands are flooded during some years, but consist mainly of grasses during dry years, and grass boundaries can change if fields are used for as haying or pasture during crop rotation. This makes accurate and consistent classification of field boundaries difficult, but we used the following general categories for field boundaries:

1. Standard: grassy field edge, staging yard, or road right-of-way (grassy strip typically 5-10m wide)

- 97 2. Wetland: permanent wetland; borders are largely unchanged from year-to-year
- 98 3. Shelterbelt: permanent windbreaks, shelterbelts, remnant forests, or shrublands
- 99 4. Other crop: annual crop or pasture with little or no visible boundary between planted areas
- 100 5. Bare: unplanted, fallow, flooded area, temporary wetland (only present for a single season),
- 101 staging yard, oil and gas equipment, or road without a planted boundary
- 102 6. Grassland: permanent seminatural grassland or pasture (not in rotation)

103 2.2. Analysis

104 Yield data from each field contains both random and systematic errors that must be modeled in
 105 order to reveal underlying changes in yield. Crop yield can vary within a field due to soil conditions,
 106 moisture, seeding rates, herbicide application, previous agricultural practices, and other factors not
 107 directly related to boundary distance. To account for this, we used additive models of the effect of
 108 boundary distance on crop yield while accounting for within-field spatial variation.

109 We fit the following model to each field-year of data:

$$\begin{aligned}
 \sqrt{Yield} &\sim Normal(\mu, \sigma) \\
 \mu &= Intercept + f(\text{Boundary Distance}, b = 5)_i + \\
 &\quad f(\text{Easting, Northing}, b = 80) \\
 \log(\sigma) &= Intercept + f(\text{Boundary Distance}, b = 5)_i + \\
 &\quad f(\text{Easting, Northing}, b = 80)
 \end{aligned} \tag{1}$$

110 • where:

- 111 1. Yield = weight of crop gathered per area of harvest (T/ha)
- 112 2. Boundary Distance = distance from field boundary type i (m)
- 113 3. Easting, Northing = distance from centre of field (m)
- 114 4. $f(x, b)$ = penalized thin-plate regression spline, where x is the predictor and b is the number of
- 115 basis dimensions

116 In addition to modeling edge effects (our variable of interest), this model also accounts for within-
 117 field spatial variation not related to edges. Spatiotemporal variation can also be modelled using a
 118 Gaussian Process Model (e.g. Kriging, SPDE Approximations) but this was computationally unfeasible

with 50,000 data points per field. Penalized splines offer a compromise, as they account for nonlinear relationships in the same way as Gaussian processes using a reduced number of dimensions. We used 5 basis dimensions for the distance smoother and 80 for the spatial smoothers, as we hypothesized that boundary effects would not be as complex as within-field variation (as in Figure 1). All models were fit in *R* using the *mgcv* library (version 1.8.38, Wood 2017), and figures were created with *ggplot2* and *ggpubr* (versions 3.3.5, Wickham 2016; and 0.4.0, Kassambara 2020).

The residuals in most of the models displayed both spatial autocorrelation in the residuals, indicating “micro-scale” variation that was not captured by the spatial smoothers (Cressie & Wikle 2011; Wikle *et al.* 2019). This is extremely common in precision yield data, and can bias standard errors of regression terms, but because a) there were a large number of data points per field, b) standard errors were relatively small (i.e. extremely small p-values), and c) results did not change with the addition of more basis functions (120 rather than 80), we decided to leave the models as-is. Temporal autocorrelation in residuals was also present, but we did not include temporal smoothers because spatial and temporal processes are confounded in precision yield data. That is, combining of fields occurs in patterns (e.g. east-to-west) so we cannot tell whether changes in yield in certain areas of the field were caused by deviations in the yield monitor sensors over time, or whether they represent changes in growing conditions. We considered the latter to be a more realistic assumption, so we assigned all random variation as spatial in nature. Non-standard combine driving patterns may be able to gather data in a way that can detect sensor drift, but this is beyond the scope of this research.

To consider results from all field-level models together, we fit models of each field-year independently and then fit overall smoothers as averages of the field-level smoothers. This does not account for uncertainty in the field-level smoothers, so we used an approach similar to bootstrapping:

1. Extract single posterior sample (*rnorm* in *R*) of smoother parameters from each field-level model using coefficient estimates and standard errors.
 2. Use posterior sample to simulate a new smoother from each field.
 3. Fit new model of simulated smoothers from all fields (with a field-year random intercept), and save this “meta-smoother.”
 4. Repeat 1000 times, and calculate coverage intervals (5-95% percentiles) on saved meta-smoothers.
- This gives coverage intervals (CIs) for the “average” smoother while accounting for field-level variability, and is conceptually similar to a meta-analysis. Spatial variability was not averaged between fields because within-field variability is not directly comparable between fields.

3. Results

3.1. Field-level example

The filtered data from each field contained a large amount of variation, but the non-stationary additive models were able to reveal underlying yield patterns. To illustrate this, we show the results from a single wheat field, where we show the relative impact of boundary distance and spatial variation on both yield mean and yield SD (“patchiness”). Figure 2a shows the filtered data collected from a single field, demonstrating a large amount of variation even after filtering. Yield mean tended to increase with distance from field boundaries while yield SD tended to decrease, but there were no consistent differences between boundary types (Figure 3). Finally, the random spatial smoothers in Figure 2b and c show that yield mean and SD systematically vary within fields, likely due to moisture, elevation, or soil conditions.

3.2. Overall results

Across all fields, standard field boundaries (grassy borders) were the most common boundary type, followed by shelterbelts and other crops (Figure S2).

Overall, both yield average and yield variability were extremely spatially dependent across all fields (average p-values both <0.0001), meaning that within-field variation was the primary driver of yield across canola, wheat, and pea crops (Table ??, row 6). Distances from boundaries were also important, but a lower proportion of the fields had strong effects (rows 1-5, cols 3 + 5).

Average canola yield tended to increase with distance from all crop boundaries, starting at 2.5 T/ha at the field edge and leveling off at about 3 T/ha (Figure 4 top row). Shelterbelt and standard boundaries were well-represented in the data, and average yield quickly increased with distance away from the field boundary, but shelterbelts had a small intermediate maximum at around 50 m before a weak decrease with distance, while average yield away from Standard field boundaries plateaued at 50 m and remained roughly constant with distance. The effect of other boundary types was less consistent, but average yield tended to increase with distance away from grassland, other crop, and wetland, and was roughly the same with distance from bare boundary types. Yield variability (Figure 4 bottom row) was essentially constant with distance for shelterbelt, standard, and other crop field boundaries, but showed some evidence of decreasing with distance from field boundary at wetlands, bare, and grassland. Interestingly, there was an intermediate reduction in canola yield variability at about 75 m away from

179 wetland boundaries, indicating a potential stabilizing effect, but this was offset by the large increase in
180 yield variability at the edge of wetlands.

181 The effect of boundary distance on average wheat yield was much more variable than the patterns
182 seen in canola yield. Average yield (Figure 5, top row) roughly increased with distance away from
183 wetland, standard, and grasslands, but both shelterbelts and bare ground displayed an intermediate
184 maximum at around 50m (similar to canola), and decreased slightly with distance from Other Crops.
185 Yield variability, on the other hand, tended to decrease with distance from bare, grassland, and wetland
186 (before 100 m, at least), increased slightly with distance from shelterbelt and standard boundaries, and
187 was roughly constant with distance from other crops (Figure 5, bottom row).

188 Pea crops were less well-represented in our data ($N = 39$ fields), and therefore the effects of
189 boundaries tended to be less consistent. Average pea yields (Figure 6, top row) were roughly 4.25
190 T/ha at the field boundary and increased to just below 5 T/ha away from shelterbelt, standard, and
191 other crop boundaries, while the effect of bare, grassland, and wetland boundaries was inconsistent.
192 Conversely, yield variability (Figure 6, bottom row) decreased with distance from grassland, shelterbelt,
193 standard, and wetland boundaries, while the pattern with distance from other crop and bare was
194 inconsistent. Unlike canola and wheat crops, there was no obvious evidence of an intermediate increase
195 in yield with distance from the field boundary.

196 4. Discussion

197 Within individual fields, both the average and variability of yield changed with distance from the
198 field boundary, and there were strong spatial relationships within each field, likely related to underlying
199 soil or moisture conditions. Mean yield tended to increase with distance from field boundaries before
200 plateauing, and there was some evidence of intermediate boosts in yield from shelterbelts next to canola
201 and wheat, while peas showed no evidence of this. However, this intermediate increase was small in
202 canola crops, meaning that ecosystem services likely did not vary strongly with distance from field
203 boundaries (Scenario 2, Figure 1). There was a fairly large (0.75 T/ha) intermediate increase in average
204 wheat yields away from shelterbelts, indicating a potential reduction in ecosystem services with distance.
205 However, there was a similar (albeit weaker) pattern associated with bare ground, so this pattern may
206 be caused by something other than the presence of shelterbelts. This indicates that shelterbelts may
207 have a positive effect on wheat yields, and future work should expand this within relevant geographic
208 sub-regions in order to locally inform growers about how best to manage the landscapes surrounding

209 their fields.

210 Our work showed an intermediate increase in wheat yield with distance from shelterbelts and bare
211 ground, but what is the cause of these patterns? We hypothesize that the potential yield-increasing
212 mechanisms may be a) microclimate effects, b) soil effects, or c) beneficial animal spillover. Shelterbelts
213 can act to capture snow and moderate downwind microclimate, reducing water stress on crop plants
214 and increasing yield (Staple & Lehane 1955; Kowalchuk & de Jong 1995; Bao *et al.* 2012). However,
215 Kowalchuk & de Jong (1995) found that positive microclimate effects of shelterbelts on wheat yield
216 occur at around 20 m (3-4 times the shelterbelt height), while our work shows a peak at around 50 m.
217 This additionally complicated by the fact that water stress varies from year-to-year, and that the impact
218 of the shelterbelt also depends on the orientation to prevailing winds and the physical structure of the
219 shelterbelt (Pelton 1967; Kort 1988; Singh *et al.* 1999). Unexpectedly, we also found this intermediate
220 yield maximum with distance away from bare field boundaries, indicating that the patterns we found
221 may be at least somewhat related to water stress. While we consider microclimate to be the most
222 likely cause of the intermediate increase, it may also be related to soil effects from shelterbelts, where
223 erosion is reduced and leaf litter from the shelterbelt can cause an increase in soil deposition (de Jong
224 & Kowalchuk 1995). Finally, shelterbelts may also act as sources of predators or parasitoids of wheat
225 crop pests (Dong *et al.* 2015; Ward *et al.* 2021) but their effect depends on pest pressures, which are
226 typically suppressed by pesticide application. We recommend that follow-up studies a) use precision
227 yield data to confirm that this pattern exists across broader geographical areas and b) examine the
228 influence of the three potential mechanisms considered above (as well as their interaction).

229 Wheat and shelterbelts aside, why did we find few consistent effects of boundary type on crop yield?
230 Our work examined only the first and last links in the causal chain *Field Boundary* \rightarrow *Ecosystem Service*
231 \rightarrow *Crop Yield*, meaning that are two mediating relationships where the overall relationship could be
232 broken or obscured. First, field boundaries may not have any influence on beneficial insect abundance
233 if separated from the larger landscape context, or spillover of beneficial organisms may be low. Second,
234 beneficial insect abundance may not influence crop yield if pest pressure or pollination deficits are
235 low, which may vary among year or location. Abiotic ecosystem services, such as reduced wind speed
236 or temperature, also depend on the structure of the boundary and whether wind or temperature are
237 limiting crop production. Our work suggests that we need to better examine the context in which
238 a) beneficial organisms spillover from field boundaries and b) under what conditions field boundaries
239 provide tangible ecosystem services (Karp *et al.* 2018). We consider these reasons below:

SNL generally has a positive effect on beneficial insect abundance, but field boundaries only represent a fraction of the SNL that surrounds a given field. Our analysis only examined boundary types, without considering the landscape context that fields were embedded in, but some studies show the influence of landscape composition at larger spatial scales (Nguyen *et al.* 2021) which could be particularly important when beneficial arthropods are disperse very broadly (Öberg *et al.* 2007). There could also be interactions between landscape composition at different scales (Mutzke *et al.* 2016; Haslem *et al.* 2021; Robinson *et al.* 2021), but this is not broadly studied. Landscape complexity (Fahrig *et al.* 2011) and connectivity are also associated with higher abundance of beneficial arthropods. This means that field boundaries such as wetlands or shelterbelts may only be helpful if connected to a larger network of non-crop habitat (but see Fahrig *et al.* 2019).

Field boundary characteristics, such as height or species composition, may play an important role in mediating spillover, but our definitions of boundaries were necessarily loose, as we used satellite imagery to manually classify them. Therefore, it may be that other aspects of field boundaries are more important for spillover of ecosystem services into fields. For example, larger or more functionally diverse (Bonifacio *et al.* 2011; Boughey *et al.* 2011; Lecq *et al.* 2018; Stašiov *et al.* 2020) hedgerows tend to support more biodiversity than smaller hedgerows, and some studies have shown that leaf litter and soil compaction influences predatory beetle communities (Sutter *et al.* 2018). These fine-scale boundary characteristics were not measured in our study, but could be used as variables in more biologically-meaningful classifications of field boundaries. Finally, the relevant spatial scale of boundary effects are often related to the height or windward orientation of the shelterbelt (Kort 1988; Kowalchuk & de Jong 1995), and precision yield data has the potential to show this in far greater detail than previous studies.

Our first scenario (Scenario 1, Figure 1) assumes that beneficial organisms disperse from boundaries into the field, and had a generally positive effect on crop yield. However, field boundaries may not have a positive effect if a) ecosystem dis-services – pest insects or weed seeds – also disperse along with beneficials, or if b) beneficials do not disperse from the boundary environment. Pests and weeds can also disperse from field boundaries, which may negate any positive effect of ecosystem services (Zhang *et al.* 2007). However, this is still poorly studied, and parsing out services from disservices is impossible using crop yield data *alone*. Ecosystem services from field boundaries may also be limited if beneficial organisms stay in field boundaries, or disperse at wider spatial scales Robinson *et al.* (2021). Lastly, pest pressure or pollination requirements may be low enough that ecosystem service provision does

not significantly change yield. Canola is largely self-pollinating (at least in hybrid canola varieties, Lindström *et al.* 2016) and wheat is wind-pollinated, meaning that slight increases in pollination services may not change yields significantly in either crop (Woodcock *et al.* 2016). Crop pests in most western Canadian fields are suppressed by insecticides (seed-treated or on the crop directly), and insect pest outbreaks tend to be temporally and spatially spotty, meaning spillover of beneficial predators and parasitoids may only matter during outbreak years.

Our work is some of the first to use a large precision yield dataset to answer questions about how landscapes influence yield. Since our sampling represents a limited amount of spatial and temporal coverage, there could be additional confounding variables that obscure signals of yield. Most fields were located in Central Alberta (Dry Mixedwood region, Natural Regions Committee 2006), where boundaries contained a higher proportion of shelterbelts (Figure S2), but differences from Southern AB (Foothills Fescue and Mixedgrass region) may be confounding the signal. Between-year effects may be important, especially during hot dry years (Kort 1988), but this was not considered in our analysis. Future work could examine whether boundaries have differing effects during hot or cool years, as shading or cooling effects may increase yield during hot years but have negative (or no) effect during cooler years. Finally, about 50% of growers in western Canada have collected precision agriculture data, and about 85% have yield monitoring capability (Steel 2017), which means that our work has only scratched the surface of what could be (collectively) one of the richest agroecological datasets ever created. We urge agronomists, growers, and ecologists to adopt more wide-spread use of precision yield data, as it represents a vast source of incredibly detailed information which can be used to answer a variety of important questions.

5. Acknowledgements

We thank Trent Clark, Dean Hubbard, Alvin French, and Kristina Polziehn for providing yield data for us, and providing insight on their yield data. We also thank Autumn Barnes and Keith Gabert of the Canola Council of Canada, and Laurel Thompson and JP Pettyjohn of Lakeland College for connecting us with farmers and agronomists.

6. Funding Sources

Funding for this research was provided by Ducks Unlimited Canada’s Institute for Wetland and Waterfowl Research, the Alberta Canola Producers Commission, Manitoba Canola Growers Association,

300 SaskCanola, the Alberta Biodiversity Monitoring Institute, and the Alberta Conservation Association.
