7    **1. Introduction**

8        Intensive agricultural production has increased over the last 100 years, and agricultural land now  
9        makes up over a third of ice-free land on Earth This has allowed increases in human population  
10      and increased (global) stability in production However, this is not without cost, as higher-diversity  
11      non-crops are converted to lower-diversity crops, resulting in loss of habitat and overall biodiversity of  
12      non-target organisms Maintaining both biodiversity and production in agroecosystems represents a  
13      seldom-considered goal of conservationists and agronomists, and hold the potential for win-win scenarios  
14      Key to this is the preservation of semi-natural land (SNL), which represents the interface between crops  
15      and non-crops within agroecosystems

16        SNL in and around crops is important for both agricultural production and conservation They are  
17        habitat for mobile organisms, and can therefore act as sources of ecosystem services such as pollination  
18        or pest control (Albrecht *et al.* (2020); Gardner *et al.* (2021)) They also can create microclimate effects  
19        that reduce extreme temperature, trap moisture, and reduce wind speed (Kort (1988)) Unfortunately,  
20        most of the research is concentrated in Europe, and they tend to be less-studied on other continents In  
21        particular, North American agroecosystems have larger fields, different crop varieties, and agronomic  
22        practices, all of which could negate or confound potential effects of SNL

23        SNL may affect yields at intermediate distances, depending on the spatial scale at which ecosystem  
24        services operate Edge effects cause low yields at the edge of crops because of sparse or late seedling  
25        emergence, poor microclimate, and competition with weeds At the same time, the centre of large fields  
26        will not receive ecosystem services if they decay with distance from edges (Kowalchuk & Jong (1995))  
27        For example, pollination services from central place foragers that nest in SNL but forage in crops  
28        drops rapidly with distance Therefore, yield may be maximized at intermediate distances, where the  
29        ecosystem services cancel out negative edge effects (e.g. Van Vooren *et al.* (2017)) This suggests a  
30        "goldilocks" field size, where negative edge effects are canceled out by ecosystem services

31        Studies of SNL effects on crop yield also suffer from limited scope (e.g. few crop types) and small  
32        sample sizes, limiting inference and reducing generality (but see wheat study) Meta-analyses have been  
33        the standard solution to this problem, but precision yield data holds enormous promise. However, its  
34        use is limited for several reasons: 1) Lack of standardized formats between equipment types, 2) Sensor  
35        calibration required for field-level accuracy, and 3) unfamiliarity with spatial statistics. Ecosystem  
36        services can influence both the mean and variability of yield in agroecosystems (Redhead *et al.* (2020)).  
37        Typically only averages (means) are considered, but higher stability (lower variance) in yield can also

38 be valuable. There are few studies of yield variability (only those with large datasets), but precision  
39 yield data opens up the possibility of modeling within-field variability, as well as average yield.

40 In this paper we ask: 1. How does crop yield change with distance from the edge of field? 2. Does  
41 this depend on type of field edge? 3. Is there an intermediate distance where yield is maximized or  
42 variance is minimized?

## 43 2. Methods

### 44 2.1. Data collection

45 Precision yield data were collected directly from farmers across Alberta. Farmers were solicited for  
46 yield data through local agronomists, and we received 298 field-years of data from 5 growers across a  
47 total of 7 years (2014-2020). We converted raw data to a standard csv format using Ag Leader SMS.  
48 72% of the crop types were either wheat (*Triticum aestivum*) or canola (*Brassica napus*), two of  
49 the most common crops in rotation in Alberta. The remaining crop types had low replication, so we  
50 constrained our analysis to only field-years containing wheat (94) or canola (119). Individual fields  
51 contained between 1 to 5 years of data (mean: 2.7), containing a total of 18.4 million data points.

52 Yield data is collected in rectangles of the same length as the data interval (distance = combine  
53 ground speed  $\times$  interval, typically 1 second) and the same width as the combine header (5-7 m, adjusted  
54 to account for overlap with adjacent swaths). We extracted the size of each polygon ( $m^2$ ), dry yield  
55 (tonnes), and the spatial location, and the sequence of collection (1 - end of harvest). Because of the  
56 large number of yield rectangles per field (30-800 thousand), we used the centroid of each polygon as  
57 its location, treating areal data as point data. Seeding and application rates were constant across fields,  
58 so we did not consider inputs in our analysis. We used dry yield (tonnes of seed/hectare minus recorded  
59 crop moisture) as our measure of crop yield. Precision yield data can be highly variable and is prone to  
60 extreme outliers (both positive and negative), especially when combine ground speeds are low and at  
61 the beginning of rows. Therefore, we filtered data that lay outside the 95th percentiles of yield within  
62 each field, values less than or equal to zero, and values outside of the 95th percentiles of ground speed.  
63 Due to the large number of data at each field, we sub-sampled to 50,000 data points per field to reduce  
64 computation time.

65 Field boundaries were automatically digitized using buffers from the yield data locations, then  
66 manually checked using satellite imagery from Google Earth and classified land cover data from AAFC.  
67 Crop boundaries are flexible, and often change yearly depending on planting and emergence conditions

68 (e.g. flooding during some years). Ephemeral wetlands are flooded during some years, but consist  
69 mainly of grasses during dry years, and grass boundaries can change if fields are used for as haying  
70 or pasture during crop rotation. This makes accurate and consistent classification of field boundaries  
71 difficult. We defined the following general categories for field boundaries: 1. Standard: grassy field edge,  
72 staging yard, or road right-of-way (grassy strip typically 5-10m wide) 2. Wetland: permanent wetland;  
73 borders are largely unchanged from year-to-year 3. Shelterbelt: permanent windbreaks, shelterbelts,  
74 remnant forests, or shrublands 4. Other crop: annual crop or pasture with little or no visible boundary  
75 between planted areas 5. Bare: unplanted, fallow, flooded area, temporary wetland (only present for a  
76 single season), staging yard, oil and gas equipment, or road without a planted boundary 6. Grassland:  
77 permanent seminatural grassland or pasture (not in rotation)

78 <!-- STANDARD -->  
79 <!-- WETLAND -->  
80 <!-- SHELTERBELT -->  
81 <!-- OTHERCROP -->  
82 <!-- BARE -->  
83 <!-- GRASSLAND -->

#### 84 2.2. Analysis

85 Yield data from each field contains both random and systematic errors that must be modeled in  
86 order to reveal underlying changes in yield. We fit an additive model of the effect of boundary distance  
87 on crop yield while accounting for within-field spatial variation and temporal variation in the data.  
88 Crop yield can vary within a field due to soil conditions, moisture, seeding rates, herbicide application,  
89 and previous agricultural practices. Ground speed is extremely important to yield monitor accuracy  
90 (Arslan & Colvin 2002), with low ground speed registering higher yields. Sensor calibration can reduce  
91 combine-level bias (such as a combine recording consistently higher/lower yields across fields), this does  
92 not address sensor drift that occurs over time. This may be caused by sensors accumulating debris  
93 during harvest (especially in canola, pers. comm. Trent Clark), leading to changes in accuracy and  
94 bias over time. To model this, we fit the following model to each field-year of data:

$$\sqrt{yield} \sim Normal(\mu, \sigma)$$

$$\begin{aligned}\mu &= Intercept + log(Polygon\ Size) + f(Edge\ Distance, b = 12)_i + \\ &\quad f(Easting, Northing, b = 60) + f(Sequence, b = 60) \tag{1} \\ log(\sigma) &= Intercept + log(Polygon\ Size) + f(Edge\ Distance, b = 12)_i + \\ &\quad f(Easting, Northing, b = 60) + f(Sequence, b = 60)\end{aligned}$$

95 • where:

- 96 1. Polygon Size = distance traveled  $\times$  width of header bar ( $m^2$ )
- 97 2. Edge Distance = distance from field edge type  $i$  (m)
- 98 3. Easting, Northing = distance from centre of field (m)
- 99 4. Sequence = order of harvest within field (1–N points)
- 100 5.  $f(x,b)$  = penalized thin-plate regression spline, where  $x$  is the predictor and  $b$  is the number of  
101 basis dimensions

102 In addition to modeling edge effects (our variable of interest), this model also accounts for a)  
103 differences in harvested area, b) within-field spatial variation not related to edges, and d) shifts in  
104 combine accuracy during harvest. Spatial or temporal variation can be modelled using a Gaussian  
105 Process Model (e.g. Kriging, SPDE Approximations) but this was computationally unfeasible with  
106 50,000 data points per field. Penalized splines offer a compromise, as they account for nonlinear "wiggly"  
107 relationships in the same way as Gaussian processes but using a reduced number of dimensions and  
108 computation time. The number of basis dimensions was checked with the *gam.check* function from  
109 *mgcv*. The relationship between polygon size and yield was modeled with a log-linear relationship with  
110 a single slope term, as this closely matched smoothed versions. Because polygon size is not intuitive,  
111 we converted it into ground speed by regressing speed on distance traveled per polygon, then using this  
112 to back-calculate the ground speed for a given polygon size (given a fixed width of header). All models  
113 were fit in *R* using the *mgcv* library (version 1.8.36, Wood 2017), and figures were created with *ggplot2*  
114 and *ggbubr* (versions 3.3.3, Wickham 2016; and 0.4.0, Kassambara 2020).

115 Despite the use of spatial and temporal smoothers, the residuals in most of the models displayed a  
116 large amount of spatial and temporal autocorrelation. *Not really sure how we can get around this. In*  
117 *practice, this means that SEs for all coefficients are too small (i.e. we gathered 1000 points, but because*

118 *they're spatially related, it's only equivalent to 100 points).*

119 To consider results from all field-level models together, we fit models independent of each other and  
120 fit an "overall" smoother as averages of the field-level smoothers. However, this does not account for  
121 uncertainty in the field-level smoothers, so we used an approach similar to bootstrapping of hierarchical  
122 mixed effects models: 1. Extract single posterior sample (*rnorm* in R) of smoother parameters from  
123 each field-level model using coefficient estimates and standard error 2. Use posterior sample to create  
124 a new smoother from each field 3. Fit new model of new smoothers from all fields, and save this  
125 "meta-smoother" 4. Repeat 1000 times, and calculate coverage intervals (5-95% percentiles) on saved  
126 meta-smoothers This gives coverage intervals (CIs) for the "average" smoother while accounting for  
127 field-level variability, and is conceptually similar to a meta-analysis. Spatial variability was not averaged  
128 between fields because differences in field geometry make it impossible to compare fields.

### 129 3. Results

#### 130 3.1. Field-level example

131 The filtered data from each field still contained a large amount of variation, but the non-stationary  
132 additive models were able to reveal underlying yield patterns. To illustrate this, we show the results from  
133 a single wheat field, where we show the relative impact of ground speed, harvest sequence, boundary  
134 distance, and spatial variation on both yield mean and yield SD ("patchiness"). Figure 1 shows the raw  
135 data collected from a single field, demonstrating a large amount of variation even among the filtered  
136 data. Combine ground speed had a large effect on both yield mean and SD, and there was also a strong  
137 effect of harvest sequence on yield mean and SD (Figure 2. Yield mean and SD tended to decrease with  
138 distance from field boundaries, but there were no consistent differences between boundary types (Figure  
139 3. Finally, the random spatial smoothers in Figure 4 show that yield mean and SD systematically vary  
140 within fields, likely due to moisture and soil conditions (Figure 4.

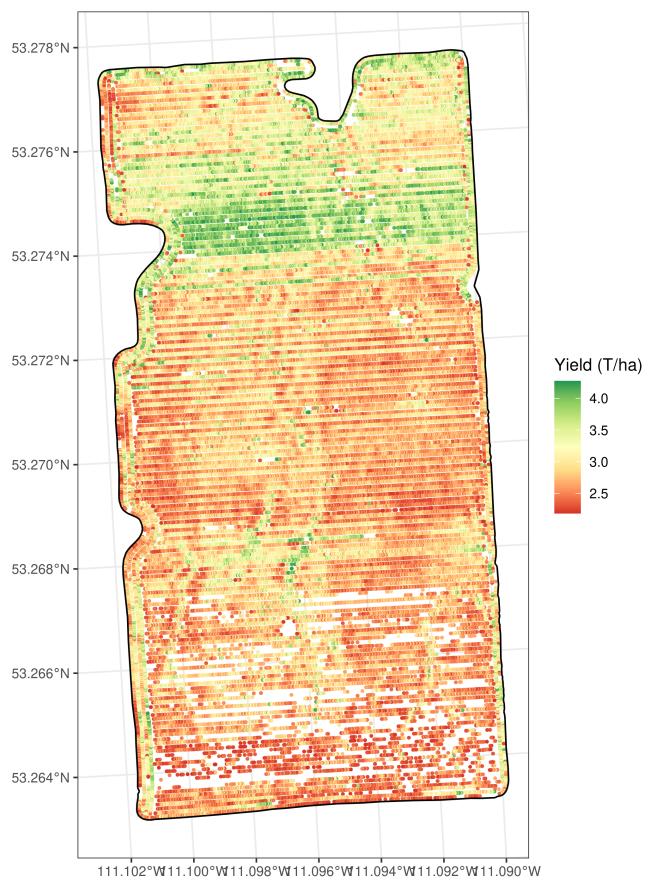

Figure 1: Example output from a single field.

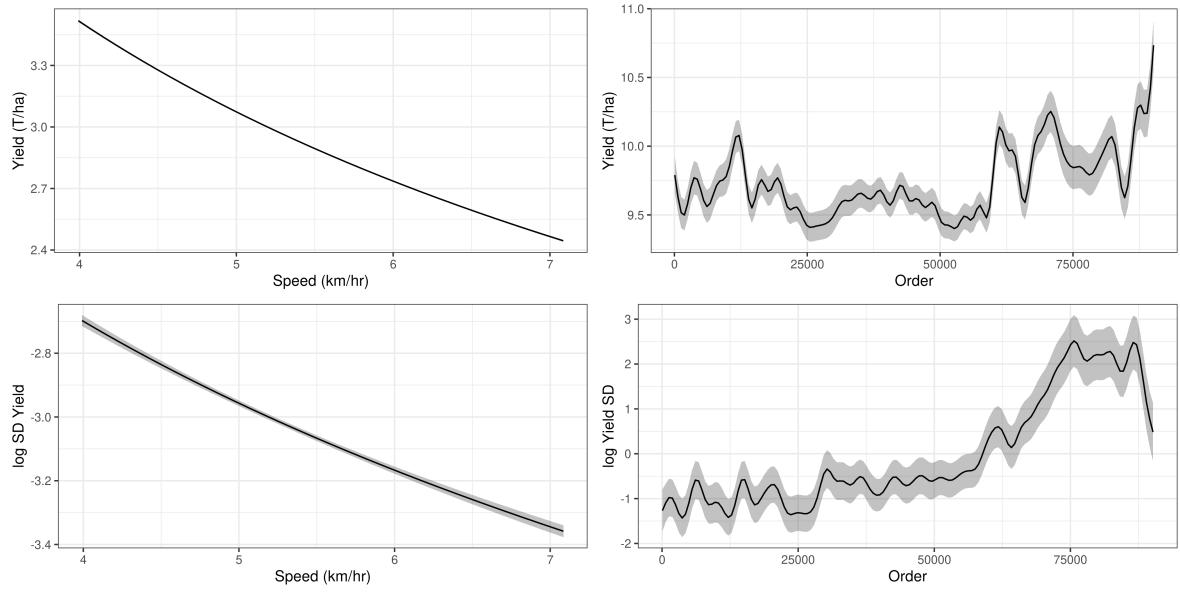

Figure 2: Ground speed and harvest sequence (random temporal variation) smoothers from a single field.

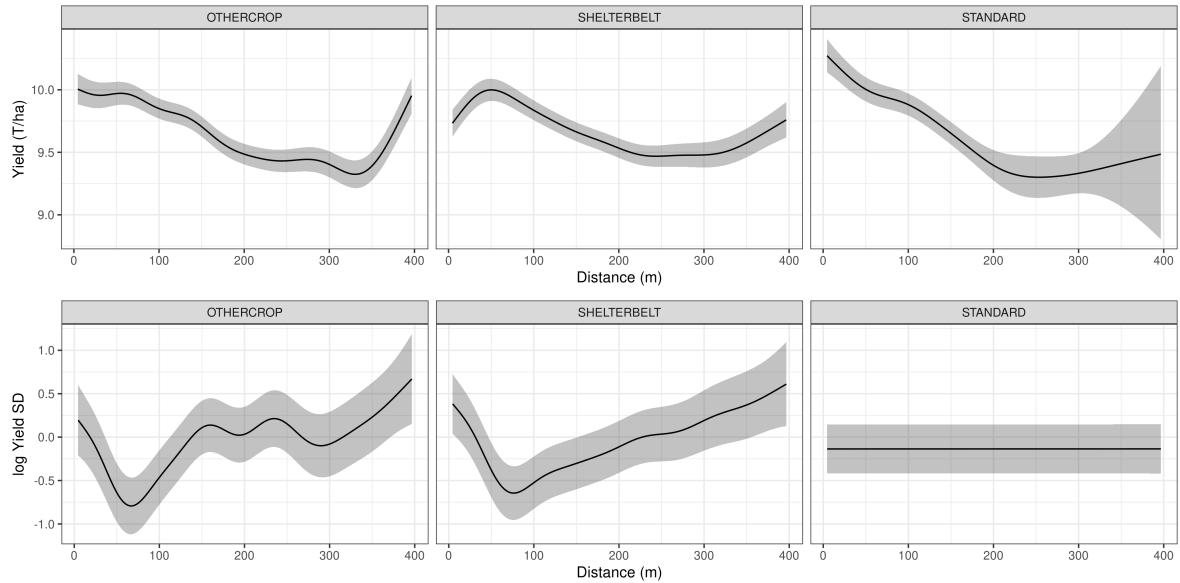

Figure 3: Distance smoothers from a single field.

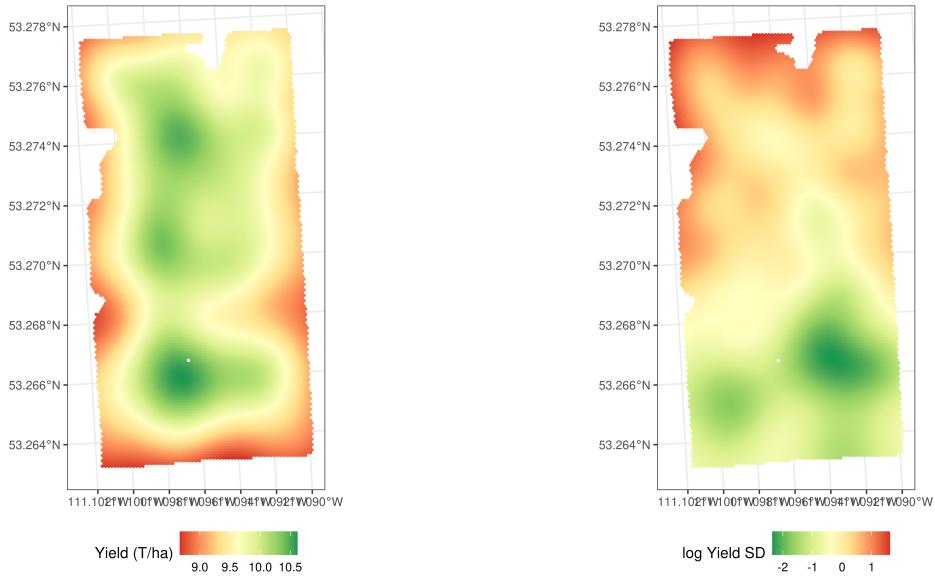

Figure 4: Spatial (random spatial variation) smoothers from a single field.

141    *3.2. Overall results*

142    Across all fields, “Standard” (grassy border) was the most common boundary type, followed by  
143    Shelterbelts and Other Crops.

144    *3.2.1. Canola fields*

145    Overall, there was a strong negative effect of combine ground speed on both the average and  
146    variability of canola yield. At the field level, both yield average and yield variability (SD of yield) of  
147    yield were extremely spatially (average p-values: 2e-16, 1.77e-05) and temporally dependent (2e-16,  
148    0.000243), meaning that average and variability changed with location in the field, as well as sequentially  
149    during the harvest. However, there was no difference in average or variability with harvest sequence  
150    when all fields were considered, meaning that combines did not appear to distort yield data from start  
151    to finish in any systematic way.

152    Average canola yield tended to increase with distance from Standard and Other Crop boundaries,  
153    leveling off at about 25 m (Figure 5 top row, Other crop and Standard panels); yield was approximately  
154    0.1 T/ha (1.5 bu/ac) lower at the edge for both of these boundary types. Interestingly, Shelterbelts  
155    were well-represented in the data (Table ??) but the negative edge effect was not strong (Figure 5 top  
156    row, Shelterbelt panel), indicating that they may provide better micro-climates for crops located near  
157    them. Other boundary types were less common in the data and had correspondingly weaker effects

158 on mean yield, but all showed a small negative edge effect. Yield variability tended to decrease with  
 159 distance from the edge of the field, indicating that edge effects contribute to yield “patchiness” as well  
 160 as averages. At Standard, Bare, and Wetland field boundaries, variability decreased until about 100 m,  
 161 after which variability was constant, while the pattern was less consistent in Grassland, Other Crop,  
 162 and Shelterbelt.

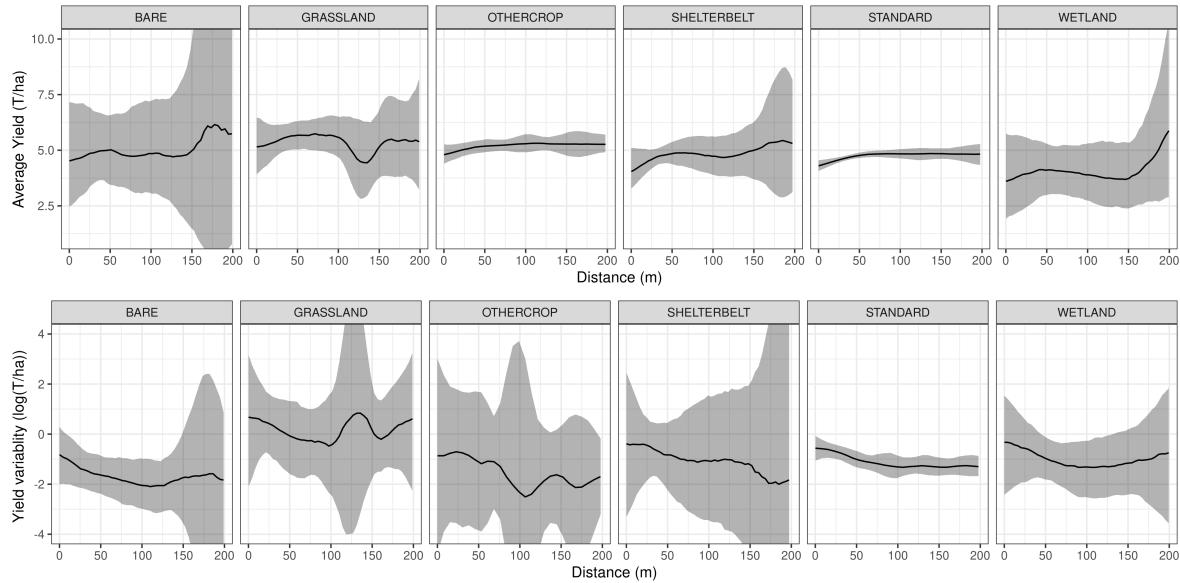

Figure 5: Field boundary effect on canola yield, accounting for the effect of combine speed, spatial variation, and harvest sequence. Upper panel represents mean yield, while the lower panel represents yield variation (i.e. "patchiness").

### 163 3.2.2. Wheat fields

164 Similar to canola, there was a strong negative effect of ground speed on both yield and variability  
 165 of wheat yield (Figure 9, left panels). At the field level, both yield average and yield variability (SD of  
 166 yield) of yield were spatially (average p-values: 2e-16, 2e-16) and temporally dependent (2e-16, 2e-16),  
 167 but harvest sequence did not distort the average or SD of wheat yield in a systematic way (Figure 9,  
 168 right panel).

169 Average wheat yield increased slightly with distance from the field boundary, but this was much  
 170 more variable than the patterns seen in canola yield (Figure 6). There was also a slight increase in  
 171 variability away from the field boundary, at least for Standard and Other Crop boundaries, but this  
 172 was inconsistent among other boundary types.

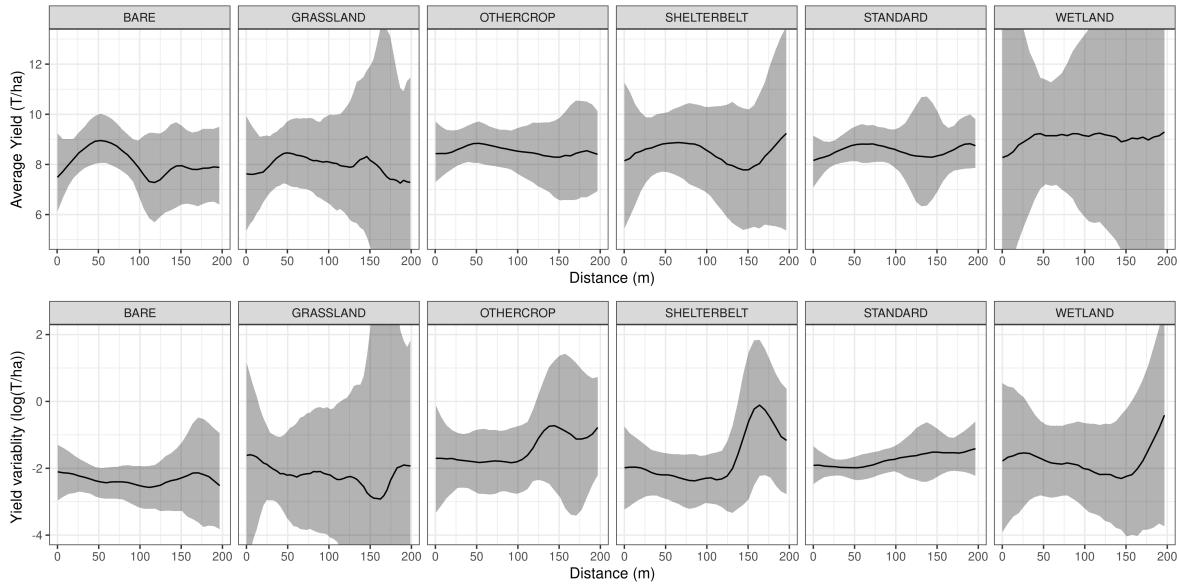

Figure 6: Field boundary effect on canola yield, accounting for the effect of combine speed, spatial variation, and harvest sequence. Upper panel represents mean yield, while the lower panel represents yield variation (i.e. "patchiness").

#### 173 4. Discussion

- 174 • Summary:
- 175 — At the level of an individual field, there were

#### 176 5. Author Contributions

177 SVJR and PG conceived of the project. SVJR collected data, conducted analysis, and wrote the  
178 manuscript.

#### 179 6. Acknowledgements

180 We thank Trent Clark, Dean Hubbard, Alvin French, and Kristina Polziehn for providing yield  
181 data for us, and providing insight on their yield data. We also thank Autumn Barnes and Keith  
182 Gabert of the Canola Council of Canada, and Laurel Thompson and JP Pettyjohn of Lakeland College  
183 for connecting us with farmers and agronomists. Funding for this research was provided by Ducks  
184 Unlimited Canada's Institute for Wetland and Waterfowl Research, the Alberta Canola Producers  
185 Commission, Manitoba Canola Growers Association, SaskCanola, the Alberta Biodiversity Monitoring  
186 Institute, and the Alberta Conservation Association.
